Canada’s craton: A bottoms-up view

Dante Canil, School of Earth and Ocean Sciences, University of Victoria, 3800 Finnerty Road, Victoria V8W 3P6, British Columbia, dcanil@uvic.ca

ABSTRACT
The origin of mantle lithosphere underlying Archean crustal provinces is most consistent with depletion at low pressures in the spinel facies under degrees of melting higher than observed in modern ocean basins. Depleted sections of the lithosphere created in convergent margin settings were underthrust and stacked to build a thick root with time. Geochronologic and geologic evidence can be interpreted to show that the final formation and amalgamation of the bulk of the “mantle root” occurs 0.5–1 b.y. later than the age of the lithosphere from which it is comprised. “Silica enrichment” is not ubiquitous in the mantle beneath Archean crustal provinces. Where it does occur, it may be a heterogeneous feature possibly imparted by marine weathering of peridotite on the Archean ocean floor before it was stacked to form a mantle root.

INTRODUCTION
Cratons are defined as stable portions of the continental plates that have escaped tectonic reworking for long periods (giga-annum [Ga]). Thirty-five Archean crustal provinces are recognized within the cratons of continents today (Bleeker, 2003). The largest mass of lithosphere beneath these cratons underlies the Moho in the mantle. Thus, the long-term strength and stability of a craton must be engendered in the properties of its mantle lithosphere, which may ultimately be tied to the origins of continents themselves.

The purpose of this review is to summarize some thermal, petrological, and geological constraints on the evolution of cratonic lithosphere as sampled by kimberlites in Canada. Canada is centered over a large craton and has the largest proportion of Archean crust in the world exposed at its surface, making it the focus of diamond exploration in the past 15 years. A significant portion of the Lithoprobe program was devoted to the geophysical imaging of lithosphere beneath the craton (Fig. 1). The geophysical surveys in this and other such programs (e.g., DeepProbe, Kaapvaal project, USArray) provide a present-day interpretation of the deep lithosphere but by themselves do not explain its origin and evolution. Mantle rocks sampled as xenoliths provide the only “in place” record of Archean and younger processes beneath cratons, hence providing us with a link between the deep lithosphere, surface geology, and geophysical data (Carlson et al., 2005).

Figure 1. Precambrian basement map of North America stripped of its Phanerozoic sedimentary cover (after Hoffman, 1988, 1990; Ross et al., 1991). Boxes show locations of various geophysical transects within the Lithoprobe program. Also shown are kimberlite fields, clusters, and pipes, clockwise from top: SI—Somerset Island; O—Otish Mountains/Renard; KL—Kirkland Lake; T—Timiskaming; WW—Wawa; L—Lake Ellen; S—Stockdale; A—Attawapiskat; K—Kyle Lake; IM—Iron Mountain; SL—State Line; W—Williams; C—Crossing Creek; FL—Fort a la Corne; BH—Buffalo Hills; D—Drybones Bay; G—Gahcho Kue; LG—Lac de Gras; J—Jericho.
PALEOGEOOTHERMS AND THE THERMAL HISTORY OF CRATONS

The cooling of the earth and the distribution of its heat sources have long been of interest (Pollack and Chapman, 1977; Verhoogen, 1956) but with few direct constraints. I examine the cooling history of cratons with a focus on the Archean Slave Province in Canada using available heat flow measurements, geochronological data, and pressure-temperature (P-T) data for xenoliths that cover a 300 km length of the province (Fig. 2). The P-T data are based on analyses from the same electron microprobe laboratory, eliminating interlaboratory inconsistency and enhancing precision.

The P-T arrays of xenoliths from the Gahcho Kue, Grizzly, and Jericho pipes in the Slave Province are identical within error of the thermobarometers applied, despite the fact that these kimberlites vary in age by 500 m.y. (Fig. 3). I fit the error of the thermobarometers applied, despite the fact that and Jericho pipes in the Slave Province are identical within inconsistency and enhancing precision.

The thermal structure of the Slave Province mantle has not changed significantly in the past 500 m.y. over a scale of ~300 km (Fig. 3). The uniform thermal structure contrasts with the petrologic structure, which varies vertically and laterally across the province. In plan view, the Slave mantle structure consists of three NE-striking ribbons of lithosphere with different levels of depletion, as deduced by garnet geochemistry (Grütter et al., 1999), that parallel slight changes in the direction of seismic anisotropy (Davis et al., 2003b) (Fig. 2). The vertical distribution of mantle peridotite in the ~180–220-km-thick lithosphere

Figure 2. Geological map of the Archean Slave Province (modified after Davis et al., 2003b; Kopylova and Caro, 2004) distinguishing Mesoarchean basement (deeper pink) from more juvenile crust to the east. Also shown are the electrical conductivity anomalies in the central Slave upper mantle (Jones et al., 2001) and northeast-trending mantle domains of varying azimuth of S-wave anisotropy (arrows) in the craton (Davis et al., 2003b; Grütter et al., 1999). Kimberlites (some labeled) are shown as blue dots.

consists of a shallow, ultradepleted layer underlain by a deeper, more fertile layer (Griffin et al., 1999a; Kopylova and Russell, 2000; Kopylova and Caro, 2004). The ultradepleted layer tapers to the southwest near Drybones Bay, where its base coincides with changes in seismic anisotropy over a narrow interval between 110 and 130 km depth (Carbno and Canil, 2002). This seismic discontinuity has been interpreted as the remnant of a lithospheric underthrust or “stack” (Bostock, 1998).

AGE OF CRATONIC MANTLE “ROOTS”

The Re-Os isotopic system has been employed extensively to estimate the age of peridotitic mantle lithosphere (Pearson, 1999). The Re/Os ratio of mantle residue decreases with melt extraction and over time evolves to low 187Os/188Os isotopic ratios. Some measure of the minimum age of the lithosphere can be made from 187Os/188Os by assuming all Re was lost on melting to produce a “Re depletion age” (TRD) of a sample. The TRD for kimberlite-borne mantle xenoliths from the Slave, Wyoming, and North Atlantic (Somerset Island) provinces
are the same as most other Archean provinces (Fig. 4). These ages established that melt extraction to form cratonic lithosphere is dominantly Archean, with some samples showing Proterozoic and younger modification (Carlson et al., 2005; Pearson, 1999). A similar age of melt extraction emerges from a whole-rock Lu-Hf isochron of peridotites in Somerset Island (Schmidberger et al., 2002).

Mantle lithosphere ages correspond with crustal ages in Archean provinces, leading to the inference that cratonic mantle roots formed and were coupled to their overlying Archean crust within a narrow time frame and have remained there ever since. This scenario poses a paradox. Several late and post-Archean events attributed to heating and/or orogenic activity are recorded in the upper and lower crust of cratons in both the Slave and Superior provinces, as indicated by late- and post-Archean ages of (1) metamorphic zircon in kimberlite-hosted lower crustal granulate xenoliths (Davis et al., 2003a; Moser and Heaman, 1997); (2) “granite blooms” in greenstone belts (Davis et al., 2003b); and (3) hydrothermal mineralization in lode gold deposits (Fig. 4). These widespread thermal events would be at odds with simultaneous development below a well-established, deep “cold” Archean lithospheric root as recorded by its Re depletion ages. Simple one-dimensional thermal modeling shows that a thermal pulse causing melting and metamorphism in the lower crust to form late granite blooms need not have thermally imprinted the entire craton root (Davis et al., 2003b). Alternatively, a recent geodynamic model proposes that cratonic lithosphere inverted its eclogite-bearing root during the latest Archean, causing melting in its lowermost crust (Percival and Pysklywec, 2007). Both of the above models hinge on when the “root” was established and stabilized.

There is some reason to recognize the resolution and limitations of the Re-Os model ages for mantle lithosphere. More than half of the Os in mantle peridotites can reside in micron-sized platinum group minerals (PGMs), which have a high-temperature stability and high partition coefficient for platinum group elements (Luguet et al., 2007). The PGMs can remain stable throughout the melting interval and may be recycled into later generations of lithosphere, accounting for the anomalously old Os ages (0.5–1.0 Ga) recorded in geologically young lithosphere in modern ocean basins (abyssal peridotites, Fig. 4). Given this attribute of the Re-Os system (Meibom et al., 2002), it is conceivable that the \( T_{RD} \) of many cratonic xenolith samples may record the Os in PGMs that have been preserved from prior (Archean) melting events but that were later recycled into younger “roots.”

Eclogite xenoliths also call into question purely Archean “root formation.” Eclogite xenoliths are interpreted by many to be representative of oceanic basaltic crust now embedded in cratonic mantle roots by lithosphere subduction or stacking (Helmsleidt and Schulze, 1989; Jacob, 2004). The eclogites occur at various depth intervals throughout the Slave province mantle root (Kopylova et al., 1999). Based on Lu-Hf and U-Pb zircon systematics, these eclogites are demonstrably younger than the majority of \( T_{RD} \) for mantle peridotites (Fig. 4), but correspond to identical ages of Paleoproterozoic subduction (ca. 2.0 Ga) recorded in surface geology at the externides of this Archean province (Schmidberger et al., 2007). If Proterozoic eclogite is a component of the root, then “root” formation must be Proterozoic even if Archean peridotite constitutes the...
bulk of the lithosphere. Thus, the age of the “root” formation may be younger than the age of the lithosphere that comprises the root. This hypothesis is consistent with U-Pb ages from lower crustal granulite xenoliths, which show that the Slave craton root cooled through the U-Pb blocking temperature of metamorphic rutile (~400 °C) to a present-day cratonic geotherm only by ca. 1.8 Ga, well after the Archean (Fig. 4). Similarly, 1.9-Ga sedimentary basins on the Slave Province record subsidence on a thinner, root-free thermal lithosphere at that time (Grotzinger and Royden, 1990).

Most intriguing is that the Re-Os ages of sulfides in kimberlite-borne diamonds sampled from the Slave Province, presumably hosted in the lithosphere, are ca. 3.5 Ga (Aulbach et al., 2004; Westerlund et al., 2006) and pre-date the NeoArchean (2.8–2.55 Ga) formation and amalgamation of overlying crust by at least 0.5 b.y.

A similar pattern is evident in the Superior Province of Canada (Stachel et al., 2006) and in Kaapvaal of southern Africa (Richardson et al., 2001). In the mantle, sulfide is molten and potentially mobile, and Os has a low closure temperature in this phase (Brenan et al., 2000), calling into question the validity of diamond ages from sulfide and other inclusions (Navon, 1999). Nonetheless, if the ages are taken at face value, they show that the formation of mantle lithosphere pre-dates its development into a craton “root” below Archean crust by 0.5–1.0 Ga.

TEKTONIC SETTING FOR CRATONIC LITHOSPHERE

Mantle lithosphere is a residue of melt extraction from peridotite, which at pressures below ~3 GPa produces olivine at the expense of all other phases and increases its Mg/Fe with depletion. This attribute of the melting process is reflected geochemically in residual peridotites by increasing Mg/Si with increasing Mg/(Mg + Fe), as exhibited by peridotites sampled in modern ocean basins, ophiolites, orogenic massifs, or continental basalt-hosted xenoliths (Fig. 5).

Most cratonic lithosphere is distinct from the latter by being depleted in Fe (high Mg#) but having variable Mg/Si (Figs. 5B and 5C) (Boyd, 1989). The compositional spectrum of low Fe and high Si in cratonic peridotites is unattainable by melting of primitive mantle peridotite at any pressure (Walter, 2005), but could be explained if they were residues of a more Si-rich and Fe-poor chondritic mantle, which has, since the Archean, escaped sampling during Proterozoic and younger melting processes (Francis, 2003). The trend to higher Si at a given Mg# could also be due to a secondary process (Herzberg, 2004; Kelemen et al., 1998).

Global data sets of all types of mantle peridotites show a covariation of Mg/Si with Al/Si that is a consequence of partial melt extraction (Pearson et al., 2003) and can be fitted to a line: \[ \frac{\text{Mg}}{\text{Mg} + \text{Fe}} \times \frac{\text{Al}}{\text{Si}} = 3.66(11) \] (95% confidence, \( r = 0.79 \)). Samples scatter to the left or right of this line have a positive or negative “\( \Delta \text{Mg}/\text{Si} \)” value. The remaining panels show all (B) cratonic spinel-facies and (C) cratonic garnet-facies mantle xenoliths.

Figure 6. Covariation of Mg/Si with Al/Si in world xenolith data set as in Figure 5. (A) shows the trend for Canadian xenoliths compared with off-craton and abyssal peridotites. The line for all off-craton xenoliths is fitted by least squares to an equation of \[ \frac{\text{Mg}}{\text{Mg} + \text{Fe}} \times \frac{\text{Al}}{\text{Si}} = 1.44(2) \] (95% confidence, \( r = 0.79 \)). Samples to the left or right of this line have a positive or negative “\( \Delta \text{Mg}/\text{Si} \)” value. The remaining panels show all (B) cratonic spinel-facies and (C) cratonic garnet-facies mantle xenoliths.
the ubiquity (or not) of Si enrichment (low Mg/Si). The ΔMg/Si for cratonic mantle as a whole is normally distributed about zero, similar to other kinds of mantle lithosphere (Fig. 7). Thus, “Si enrichment” in cratonic mantle is an exception, occurring in a minority of samples. Indeed, the lower Mg/Si (or negative ΔMg/Si) observed in some cratonic peridotites is prevalent mostly in South Africa (Fig. 7). In modern abyssal peridotites, low Mg/Si at a given degree of depletion is a consequence of seafloor exposure and marine weathering (Snow and Dick, 1995). It appears possible that the lower Mg/Si (i.e., Si enrichment, negative ΔMg/Si) in some cratonic mantle is due to marine weathering, if its protoliths were at one time exposed to Archean seawater and later subducted to form a craton root.

Unlike Si enrichment, Fe depletion in cratonic mantle is ubiquitous (Fig. 5). Given current experimental data, generating the low Fe in cratonic peridotites from primitive mantle sources can only occur by melting at high pressures (>5 GPa; Walter, 2003). This has led to the belief that cratonic mantle is a residue of high-pressure melting in plumes and attaches to the craton root vertically by “plume subcretion” (Aulbach et al., 2007; Griffin et al., 1999a). This mode of origin at pressures >5 GPa is inconsistent with a number of trends in Cr, Al, and mildly incompatible elements in peridotite, which preclude extensive melting at pressures greater than 3 GPa (Canil, 2004; Canil and Wei, 1992; Kelemen et al., 1998; Kesson and Ringwood, 1989; Stachel et al., 1998).

If produced at low pressure, low Fe in cratonic peridotites requires either a source with higher Mg# or melting under conditions that greatly change the distribution of Fe from Mg. Because Fe$^{3+}$ is ten times more incompatible than Fe$^{2+}$ (Canil et al., 1994), melting at higher oxygen fugacity ($f_O_2$) results in a residue with higher Mg/Fe for a given degree of melting. No experimental studies directly investigate the effect of $f_O_2$ on major element systematics (Mg/Fe) of mantle melting, but this effect can be examined using the behavior of vanadium (V), which is mildly incompatible and redox sensitive (Canil, 2002). The lower V at a given degree of depletion in many cratonic peridotites could result from melting at higher $f_O_2$. If this is correct, then by analogy with modern settings, the mantle now beneath Archean crustal provinces was generated in the upper plate of a convergent margin, consistent with a “stack” origin.

The lack of correlation of Mg# in olivine with modal olivine also distinguishes cratonic peridotites from Phanerozoic or
off-craton peridotites (Fig. 5), and the lack of correlation can only occur by melting to near or beyond orthopyroxene exhaustion (~40%) (Bernstein et al., 2007). This means the upper spinel facies portion of cratonic lithosphere was originally a nearly dunitic residue. This trend to extremely depleted lithosphere at the shallowest levels in the lithospheric column beneath cratons is evident in xenolith data sets from the Slave Province (Aulbach et al., 2007; Kopylova and Russell, 2000) and is an almost universal observation in mantle columns constructed from kimberlite-hosted garnet xenocrust suites elsewhere in Canada and throughout the world (Canil et al., 2003; Gaul et al., 2000; Griffin et al., 1999b; Scully et al., 2004). The highly depleted shallow levels of mantle lithosphere beneath Archean provinces provide the compositional buoyancy required to support their cratonic roots against removal into the convecting mantle (Jordan, 1975, Lee, 2003; Poudjom Djomani et al., 2001).

SUMMARY

The weight of thermal, petrologic, and geological evidence points toward an origin for lithosphere beneath Archean provinces in a convergent margin. Most of that lithosphere is Archean in age, but many lines of evidence show that the deep lithosphere beneath these regions did not “stack” or stabilize a “root” until at least 0.5 by. later. If so, was Archean crust tectonically emplaced atop the mantle lithosphere in a stack that in North America is more appropriately described as early Proterozoic in age? Why does lithospheric stacking not occur today? Did plate thicknesses and lengths in the Precambrian differ enough from the present-day to engender a more neutral buoyancy, required for shallow subduction and “stacking” (Davies, 1992)? The level of depletion in mantle roots seems the key, but more sluggish plate tectonics proposed for the Archean (Korenaga, 2006) may also be part of the answer. Slower plates and fewer convergent margins with a smaller proportion of early continents may explain the time lag of 0.5–1 by. between lithospheric age and the age of actual mantle “root” or “stabilization.” Better chronometry of mantle rocks would help test this idea but is made difficult by their equilibration above the closure temperatures of many isotopic systems.

This challenge is also an opportunity. The cooling rates of the continents and the transient thermal signals therein (Michaut and Jaupart, 2007) have the potential to be understood by the different closure properties for different isotopic systems in mantle minerals from cratonic xenoliths (Bedini et al., 2004). Further correlation of geophysical and geological observations to the petrology and geochronology of xenoliths in cratons densely sampled by kimberlites can address these questions.
